Network devices can be broadly divided into three categories: 1) signal processing devices; 2) switching devices; and 3) transmission devices. Signal processing devices, which can include interfaces, combiners, switches, line cards, and the like, can perform the various signal processing functions performed in telecommunications network to enable a communications path between two endpoints. Switches, which can include routers, can be used to redirect communications from one link to another. Transmission devices, which can include amplifiers, lasers, and the like, can provide telecommunications signals over the links. Generally, transmission devices are not capable of processing and switching the received signals. However, for transmitting the signals, some transmission devices are capable of operating in a switch mode. Thus, transmission devices can be functionally characterized as having two parts: a) a transmission path; and b) signal processing hardware to enable the transmission path. A telecommunications network can include a number of different network devices. In order

to maintain a quality of service for communications throughout the network, the amount of processing that is to be performed on each individual signal is known. The network devices are then programmed to operate at their maximum processing rate. If there is an overload in the network devices, the amount of signal processing can increase. During the operation of network devices, conditions can occur when higher order functions begin to predominate in either side of the device. These higher order functions can cause overloading of the device and result in decreased QoS. This can result in loss of capacity at a large scale because all these additional functions are performing as expected, until overloading occurs. High capacity applications have grown by 10% or more each year for the past 20 years. Sustained growth rate of this magnitude is often referred to as “big bang” growth and is indicative of the need
